Abstract

A constitutive model is derived for the time-dependent response of particle-reinforced elastomers at finite strains. An amorphous rubbery polymer is treated as a network of long chains linked by permanent junctions (chemical crosslinks, entanglements and filler particles). A strand between two neighboring junctions is thought of as a sequence of mers whose motion is restricted to some tube by surrounding macromolecules. Unlike the conventional approach that presumes the cross-section of the tube to be constant, we postulate that its radius strongly depends on the longitudinal coordinate. This implies that a strand may be modeled as a sequence of segments whose thermal motion is totally frozen by the environment (bottle-neck points of the tube) bridged by threads of mers which go through all possible configurations during the characteristic time of a test. Thermal fluctuations affect the tube's radius, which results in freezing and activation of regions of high molecular mobility (RHMs). The viscoelastic response of an elastomer is associated with thermally activated changes in the number of RHMs in strands. Stress-strain relations for a rubbery polymer at finite strains and kinetic equations for the concentrations of RHMs are developed by using the laws of thermodynamics. At small strains these relations are reduced to the conventional integral constitutive equation in linear viscoelasticity with a novel scaling law for relaxation times. The governing equation is determined by 5 adjustable parameters which are found by fitting experimental data in tensile dynamic tests on a carbon black filled natural rubber vulcanizate.

Key-words: Particle-reinforced elastomers, Viscoelasticity, Tube concept, Thermal fluctuations, Dynamic tests

1 Introduction

This study is concerned with the viscoelastic behavior of unfilled and particle-reinforced rubbers in isothermal tests. The time-dependent response of elastomers and rubbery polymers has attracted essential attention in the past decade, which may be explained by numerous applications of rubber-like materials in industry (vehicle tires, shock absorbers, earthquake bearings, seals, flexible joints, solid propellants, etc.). Despite noticeable progress in this field (see, e.g., Govenjee and Simo, 1992; Ozupek and Becker, 1992; Gonzonas, 1993; Johnson and Stacer, 1993; Le Tallec et al., 1993; Zdunek, 1993; Hausler and Sayir, 1995; Johnson et al., 1995; Aksel and Hübner, 1996; Holzapfel and Simo, 1996; Lion, 1996, 1997, 1998; Spathis, 1997; Bergström and Boyce, 1998; Ha and Schapery, 1998; Reese and Govinjee, 1998; Septanika and Ernst, 1998a,b; Ernst and Septanika, 1999; Mieche and Keck, 2000; Wu and Liechti, 2000; Haupt and Sedlan, 2001), some important questions remain, however, obscure.

Numerous observations in uniaxial and biaxial tests evidence that commercial rubbery vulcanizates reinforced with carbon black and silica, as well as solid propellants filled with micrometer-size hard particles demonstrate a pronounced time-dependent response which may be associated with their viscoelastic properties. For examples, we refer to recent studies by Hausler and Sayir (1995), Lion (1996–1998), Bergström and Boyce (1998), Septanika and Ernst (1998b), Mieche and Keck (2000), Wu and Liechti (2000), and Haupt and Sedlan (2001). An unresolved problem remains about the mechanism for stress relaxation at the molecular level.

To answer this question, Aksel and Hübner (1996) carried out tensile relaxation tests on crosslinked polybutadiene rubber reinforced with glass beads at ambient temperature with various volume fractions of filler (from 0 to 45 %). Observations evidenced that there was no relaxation in the unfilled rubber, and the level of relaxed stress increased with the content of reinforcement. They suggested that slippage of polymeric chains along the filler surface may serve as a mechanism for stress relaxation in the linear regime, whereas detachment of chains from the surfaces of beads and creation of voids characterized the nonlinear viscoelasticity of rubber.

Liang et al. (1999) reported experimental data in dynamic tensile tests (with frequency 1 Hz) on ternary composite of polypropylene and EPDM (ethylene propylene diene monomers) elastomer filled with glass beads. They demonstrated that (i) treatment of beads by silane coupling agent did not affect the mechanical damping of specimens (measured in terms of the loss modulus) and (ii) the loss modulus of the compound with untreated beads decreased with the concentration of filler [in contrast with the observations by Aksel and Hübner (1996)].

These conclusions were recently questioned by Leblanc and Cartault (2001), who measured dynamical shear response of uncured styrene-butadiene rubber reinforced with various amounts of carbon black and silica and found that the compounds exhibited practically no viscoelasticity or rather limited time-dependent response. This implies that crosslinks play the key role in viscoelasticity of rubber, while the effect of filler particles is relatively weak.

Clarke et al. (2000) carried out tensile relaxation tests on two unfilled elastomers (natural polyisoprene rubber with polysulphur crosslinks and synthetic polyacrylate rubber with carbon-carbon and carbon-oxygen crosslinks) at the temperature $T = 80$ °C. At a relatively small strain ($\epsilon = 0.05$) the natural rubber demonstrated significant mechanical relaxation (which is observed during at least 10^6 s), whereas the synthetic elastomer revealed no relaxation. Clarke et al. (2000) associated slow relaxation of natural rubber with isomerisation of polysulphur crosslinks, but could not explain stress relaxation in natural rubber observed in short-term mechanical tests, as well as its absence in polyacrylate elastomer.

Two approaches may be mentioned to the description of the time-dependent response in rubbery polymers. The first was proposed about half a century ago by Green and Tobolsky (1946) and, afterwards, revised by Yamamoto (1956), Lodge (1968) and Tanaka and Edwards (1992), to mention a few, and applied to describe the viscoelastic behavior of rubbery polymers by Drozdov (1997) and Ernst and Septanika (1999). According to the concept of transient networks, a rubbery polymer is modeled as a network of long chains bridged by temporary junctions (which are associated with chemical and physical crosslinks and entanglements). A strand whose ends are linked to neighboring junctions is treated as an active one. Snapping of an end of a strand from a junction (breakage of a crosslink or disentanglement of a chain) is thought of as its breakage (transition from the active state of the strand to its dangling state). When a dangling chain captures a junction (which reflects creation of a new physical crosslink or entanglement), a new active strand merges with the network. Breakage and reformation of active strands are treated as thermally activated processes: attachment and detachment events occur at random times as they are agitated by thermal fluctuations. A disadvantage of this model is that it does not explain observations by Leblanc and Cartault (2001): the theory of transient networks implies an increase in the strength of relaxation in reinforced rubbery compounds independently of the degree of crosslinking, because particles of filler play the role of extra junctions in the network. It is worth mentioning two shortcomings of this theory from the theoretical standpoint: (i) it associates viscoelasticity with the micro-motion of strands, which contradicts the conventional opinion that relaxation of stresses reflects *local* segmental motion in the chain backbone (Sperling, 1996), and (ii) this approach is grounded on the hypothesis that the stress-free state of a reformed strand coincides with the deformed state of the network at the instant of their merging. The latter is tantamount to implicit ascribing some elastic features to long chains [see a recent discussion of this issue for microemulsions with telechelic polymers in Filali et al. (2001)], whereas the conventional theory of rubber elasticity disregards the contribution of mechanical energy into the free energy of chains compared to that of configurational entropy (Treloar, 1975).

The other concept was recently suggested by Clarke et al. (2000) who associated the viscoelastic behavior of elastomers with mechanically induced rearrangement (isomerisation) of crosslinks. The shortcomings of this approach are that (i) it contradicts experimental data by Aksel and Hübner (1996) (because it disregards the effect of filler) and (ii) this model does not explain the presence of different relaxation modes observed in a number of mechanical tests (because crosslinks are identical, their

rearrangement results in a unique relaxation time inversely proportional to the characteristic time of rearrangement), and (iii) it fails to describe the viscoelastic behavior of uncrosslinked polymers (uncured rubbers or thermoplastics above the glass transition temperature).

The objective of this study is three-fold: (i) to develop a micromechanical model which does not contradict the above experimental data, (ii) to find adjustable parameters in constitutive equations by fitting observations in dynamic tests with a wide range of frequencies (3 decades) at various temperatures (from -20 to 100 °C), and (iii) to demonstrate that the material constants are altered with temperature in a physically plausible way. By no means this model is treated as an alternative for existing theories, but rather as an accompanying concept. This is a reason why we focus on observations in short-term tests (the frequency, f , changes from 10^{-1} to 10^2 Hz) with relatively small strains (less than 10 %), by assuming that (i) the theory of transient networks with mechanically induced rates for breakage and reformation of active strands can correctly predict experimental data in the region of larger strains, where disentanglement of chains and dewetting of the host polymer from the filler surfaces become essential, and (ii) the theory of junctions' rearrangement can be adequately applied to the analysis of the time-dependent response in long-term tests (with the characteristic time of the order of 10^6 s).

At first glance, approximation of experimental data in isothermal dynamic tests with small strains is an oversimplified task. Assuming the stress, $\sigma(t)$, at an arbitrary time $t \geq 0$ to depend linearly on the strain history, $\epsilon(\tau)$, $\tau \in [0, t]$, and referring to the Riesz theorem for the presentation of a linear functional, one can write

$$\sigma(t) = E \left[\epsilon(t) - \int_0^t R(t - \tau) \epsilon(\tau) d\tau \right], \quad (1)$$

where E is an elastic modulus and $R(t)$ is a relaxation kernel. Expanding the function $R(t)$ into a truncated Prony series,

$$R(t) = \sum_{N=1}^{N_1} \xi_N \exp\left(-\frac{t}{\tau_N}\right), \quad (2)$$

one finds that given a number of terms, N_1 , and a series of relaxation times, τ_N , the parameters E and ξ_N may be uniquely determined by matching the storage and loss moduli with the help of the least-squares algorithm. This approach perfectly works when we aim to *approximate* observations at some temperature and amplitude of oscillations. In a more complicated case which is addressed here, when observations are available at several temperatures and amplitudes of strains (the response of particle-reinforced rubber vulcanizates is extremely sensitive to the amplitude of oscillations even for strains of the order of several per cent) and the objective is to *evaluate* the effect of thermomechanical factors on material parameters, phenomenological equations (1) and (2) totally fail, because they provide no information about changes in the relaxation times, τ_N , with temperature and strain.

To shed some light on the effects of temperature and strain on the relaxation spectrum, we develop a model for the time-dependent response of elastomers at finite strains (i) that is reduced to Eq. (1) in the case of small strains, and (ii) which expresses the quantities ξ_N and τ_N in Eq. (2) in terms of some micromechanical parameters, whose dependence on thermomechanical factors appears to be physically plausible. This model contains only five material constants which are determined by fitting observations.

According to the statistical theory of macromolecules, a rubbery polymer is thought of as a network of long chains linked by permanent junctions (crosslinks, entanglements and van der Waals forces). A strand between two neighboring junctions is thought of as a set of large number of mers connected in sequel. The classical theory of rubber elasticity treats an individual strand as an object independent of its surrounding, which implies that the configurational entropy (associated with the number of configurations available for statistically independent segments in the strand) provides the main contribution into the free energy per strand. It was recognized four decades ago that micro-motion of segments is confined to the neighborhood of some "mean configuration" by surrounding macromolecules which suppress their thermal fluctuations. This confinement is traditionally accounted for in the framework of the tube concept which presumes that a chain can freely move only within some tube created by neighboring macromolecules (Doi and Edwards, 1986). For a detailed discussion of constrained fluctuations, the reader is referred to Everaers (1998).

The tube is conventionally treated as a curvilinear cylinder with a constant cross-sectional area. The main hypothesis of the present study is that small-scale local heterogeneities dramatically affect micro-

motion of a strand, which implies that the radius of the cylinder strongly depends on the longitudinal coordinate. This means that the surface of the cylinder is extremely wavy, and the tube may be treated as a sequence of regions with high mobility of segments bridged by bottle-neck regions, where the molecular mobility is strongly suppressed. The sketch depicted in Figure 1 demonstrates the position of the tube and the location of regions of high mobility (RHMs) linked by regions of suppressed mobility at the current time t . Thermal fluctuations of surrounding macromolecules change the positions of RHMs noticeably even after a small interval of time, Δt , which implies that the current properties of a strand may be described in terms of the statistical distribution of RHMs only.

To make the model tractable, we introduce the distribution, p_N , of strands with various numbers of RHMs, N , in an equilibrated sample (in the stress-free state at time $t = 0$). Application of external loads activates the network, which implies that the concentrations of RHMs in strands are altered. At an arbitrary instant $t \geq 0$, the state of a strand (which initially has N RHMs) is described by the current number of regions of high mobility, $N_a(t)$. Suppression of RHMs by surrounding molecules, as well as activation of frozen segments (agitated by thermal fluctuations occurring at random times) are assumed to serve as a basic mechanism for the viscoelastic response of an elastomer at the micro-level.

The study is organized as follows. Deformation of a strand is described in Section 2. The mechanical energy of a network is determined in Section 3. Stress-strain relations at finite strains and a kinetic equation for the function $N_a(t)$ are derived in Section 4 by using the laws of thermodynamics. The constitutive equations are simplified for the case of small strains in Section 5. Uniaxial tension of a specimen is analyzed in Section 6. Results of numerical simulation are compared with observations in dynamic tests on a carbon black filled natural rubber vulcanizate in Section 7. The experiments exposed in the introductory section are shortly discussed in terms of the model in Section 8. Some concluding remarks are formulated in Section 9.

2 Deformation of a strand

We consider a strand linking two junctions, A_1 and A_2 , which contains N regions of high molecular mobility in the stress-free state at the initial instant $t = 0$ and $N_a(t)$ RHMs at time $t \geq 0$. Introducing the dimensionless increment of the number of RHMs,

$$n(t) = \frac{N - N_a(t)}{N},$$

we find that

$$N_a(t) = N[1 - n(t)]. \quad (3)$$

It is worth noting that the function $n(t)$ may accept both positive ($N_a(t) < N$) and negative ($N_a(t) > N$) values.

Let e be a strain from the stress-free state of a strand to its deformed state. Assuming that suppressed regions are not deformed, we find that the strain e equals the sum of strains for active RHMs,

$$e = N_a e_a.$$

This equality together with Eq. (3) implies that

$$e_a = \frac{e}{N(1 - n)}. \quad (4)$$

The mechanical energy of suppressed regions (totally frozen segments of a strand) is assumed to vanish. Active RHMs are modeled as linear elastic solids with the strain energy

$$\frac{1}{2} \mu e_a^2, \quad (5)$$

where the rigidity per bond μ has the dimension of energy. Two remarks are necessary regarding Eq. (5). First, this relation presumes small deformations of RHMs. This hypothesis was confirmed by recent molecular dynamic simulations (Bergström and Boyce, 2001) which demonstrated that axial elongation

of a specimen with macro-strains up to 100 % implied micro-strains per node which did not exceed 5 % (for chains containing 200 atoms, which is in quantitative agreement with data obtained by fitting observations in our study, see Section 7). Second, at small strains, the contributions of mechanical and statistical elasticity into the free energy of a polymer cannot be distinguished (Ferry, 1980), which implies that $\mu = \mu(T)$ is the rigidity associated with both (entropic or mechanical) components of the potential energy of deformation.

The strain energy of a strand, w_N , is determined as the sum of the strain energies for individual RHMs. It follows from Eqs. (4) and (5) that

$$w_N(e) = \frac{1}{2} \mu N_a e_a^2 = \frac{\mu e^2}{2N(1-n)}. \quad (6)$$

To express the strain in a strand, e , in terms of the Cauchy deformation tensor for the network, $\hat{C}$, we suppose that in the stress-free state the strand has a small end-to-end length δ_N and it is directed along the unit guiding vector $\bar{l}$,

$$\bar{r}_2^\circ - \bar{r}_1^\circ = \delta_N \bar{l},$$

where $\bar{r}_1^\circ$ and $\bar{r}_2^\circ$ are initial radius vectors of the end points, A_1 and A_2 . At some instant $t \geq 0$, the junctions occupy points with the radius vectors

$$\bar{r}_1(t) = \bar{r}_1^\circ + \bar{u}(t, \bar{r}_1^\circ), \quad \bar{r}_2(t) = \bar{r}_2^\circ + \bar{u}(t, \bar{r}_2^\circ),$$

where $\bar{u}(t, \bar{r})$ is the displacement vector at point $\bar{r}$ for transition from the stress-free state to the deformed state at time t . The current position of the strand is determined by the end-to-end vector

$$\bar{R}(t) = \bar{r}_2(t) - \bar{r}_1(t) = \delta_N \bar{l} + [\bar{u}(t, \bar{r}_1^\circ + \delta_N \bar{l}) - \bar{u}(t, \bar{r}_1^\circ)].$$

Neglecting terms beyond the first order of smallness compared to δ_N , we find that

$$\bar{R}(t) = \delta_N \bar{l} \cdot [\hat{I} + \bar{\nabla}^\circ \bar{u}(t, \bar{r}_1^\circ)],$$

where $\bar{\nabla}^\circ$ is the gradient operator in the stress-free state, $\hat{I}$ is the unit tensor and the dot stands for inner product. In terms of the radius vector in the actual state, $\bar{r}$, this equality reads

$$\bar{R}(t) = \delta_N \bar{l} \cdot \bar{\nabla}^\circ \bar{r}(t) = \delta_N [\bar{\nabla}^\circ \bar{r}(t)]^\top \cdot \bar{l}, \quad (7)$$

where $\top$ stands for transpose. The end-to-end length of the strand, ds , is given by

$$ds^2 = \bar{R} \cdot \bar{R}.$$

It follows from this equality and Eq. (7) that

$$ds^2(t, \bar{l}) = \delta_N^2 \bar{l} \cdot \hat{C}(t) \cdot \bar{l}, \quad (8)$$

where

$$\hat{C}(t) = \bar{\nabla}^\circ \bar{r}(t) \cdot [\bar{\nabla}^\circ \bar{r}(t)]^\top \quad (9)$$

is the Cauchy deformation tensor for transition from the stress-free state of the network to its deformed state at time t .

The extension ratio for a strand, λ , equals the ratio of the current end-to-end length, ds , to that of the strand in an “activated” stress-free state, ds° . The latter state is a state of the strand which is suddenly unloaded, but for which the number of RHMs coincides with its current value, $N_a(t)$. It differs from the equilibrium stress-free state of the strand, where the number of RHMs equals N . The difference between the end-to-end lengths of the strand in the activated state, $ds^\circ(t)$, and in the equilibrium state, $ds(0) = \delta_N$, determines the end-to-end elongation driven by changes in the number of RHMs. We assume that the transformation-induced end-to-end elongation of a chain is proportional to the number of frozen RHMs, $N - N_a(t)$, which implies that

$$ds^\circ(t, \bar{l}) = \delta_N + N n(t, \bar{l}) \delta^\circ, \quad (10)$$

where δ° is an increment of the end-to-end length driven by transition of an individual RHM. It follows from Eqs. (8) and (10) that

$$\lambda(t, \bar{l}) = \frac{ds(t, \bar{l})}{ds^\circ(t, \bar{l})} = \frac{[\bar{l} \cdot \hat{C}(t) \cdot \bar{l}]^{\frac{1}{2}}}{1 + \eta_N n(t, \bar{l})}, \quad (11)$$

where

$$\eta_N = \frac{N\delta^\circ}{\delta_N}.$$

Adopting the conventional hypothesis in rubber elasticity (which is tantamount to the assumption about statistical independence of RHMs, see Treloar, 1975) that

$$\delta_N = \tilde{\delta}\sqrt{N},$$

where the coefficient $\tilde{\delta}$ is independent of N , we arrive at the formula

$$\eta_N = \tilde{\eta}\sqrt{N}, \quad \tilde{\eta} = \frac{\delta^\circ}{\tilde{\delta}}. \quad (12)$$

The strain in a strand is determined by the Hencky formula

$$e = \ln \lambda.$$

Substitution of expression (11) into this relation implies that

$$e(t, \bar{l}) = \frac{1}{2} \ln [\bar{l} \cdot \hat{C}(t) \cdot \bar{l}] - \ln [1 + \eta_N n(t, \bar{l})]. \quad (13)$$

Equation (13) establishes correspondence between the micro-deformation of a strand which is described by the strain, e , and the macro-deformation of a network which is determined by the Cauchy deformation tensor, $\hat{C}$. The parameter η_N in Eq. (13) may serve as a measure of coiling for strands: for strongly coiled chains, transformation-induced elongation of a strand is negligible compared to its length and η_N is close to zero, whereas for uncoiled chains η_N has the order of unity.

3 Strain energy density of a network

In the stress-free state a rubbery polymer is modeled as a network of strands with various numbers of RHMs ($N = 1, 2, \dots, N_1$), where N_1 is the maximal number of regions of high mobility per strand. Denote by Ξ_N the concentration (per unit mass) of strands with N RHMs (in thermal equilibrium in the stress-free state) and by

$$\Xi = \sum_{N=1}^{N_1} \Xi_N$$

the total number of strands per unit mass. The distribution of strands is characterized by the function

$$p_N = \frac{\Xi_N}{\Xi}.$$

Referring to the random energy model (see, e.g., Dyre, 1995), we accept the quasi-Gaussian ansatz for the probability density p_N ,

$$p_N = A \exp \left[-\frac{(N - \tilde{N})^2}{2\Sigma^2} \right], \quad (14)$$

where $\tilde{N}$ and Σ are positive constants, and the parameter A is determined by the condition

$$\sum_{N=1}^{N_1} p_N = 1.$$

When $\tilde{N} \gg \Sigma$, we can identify $\tilde{N}$ with the average number of RHMs in a strand and Σ with the standard deviation of the number of RHMs.

We accept the conventional assumption that the excluded-volume effect and other multi-chain effects are screened for an individual chain by surrounding macromolecules (Everaers, 1998). This implies that the energy of interaction between strands may be neglected (under the hypothesis of incompressibility) and the strain energy of the network may be determined as the sum of the potential energies of deformation for individual strands. Assuming the distribution of strands with various guiding vectors to be isotropic, we find the concentration (per unit mass) of strands with N RHMs and guiding vector $\bar{l}$,

$$X_N(\bar{l}) = \frac{1}{4\pi} \Xi p_N \sin \vartheta d\vartheta d\varphi, \quad (15)$$

where ϑ and φ are Euler's angles that determine the position of the unit vector $\bar{l}$. Multiplying the number of strands, $X_N(\bar{l})$, by their mechanical energy, w_N , summing the results for various N and $\bar{l}$, and using Eqs. (6) and (15), we find the strain energy of the network

$$W(t) = \frac{\mu \Xi}{8\pi} \sum_{N=1}^{N_1} \frac{p_N}{N} \int_0^{2\pi} d\varphi \int_0^\pi \frac{e^2(t, \vartheta, \varphi)}{1 - n(t, \vartheta, \varphi)} \sin \vartheta d\vartheta. \quad (16)$$

Our purpose now is to find the derivative of the function W with respect to time. Because the parameters μ , Ξ and p_N are, in general, functions of temperature, T , the derivatives of these quantities should be accounted for in the calculation of dW/dt for an arbitrary thermo-mechanical process. To simplify the analysis, we confine ourselves to small changes in temperature and presume that the concentrations of strands, Ξ_N , with various numbers of RHMs, N , are affected by temperature rather weakly. This implies that only the derivative of the average rigidity per bond, μ , is taken into account in the formula for the derivative of W . Differentiation of Eq. (16) results in

$$\frac{dW}{dt}(t) = \frac{\mu \Xi}{4\pi} \sum_{N=1}^{N_1} \frac{p_N}{N} \int_0^{2\pi} d\varphi \int_0^\pi \frac{e(t, \vartheta, \varphi)}{1 - n(t, \vartheta, \varphi)} \frac{\partial e}{\partial t}(t, \vartheta, \varphi) \sin \vartheta d\vartheta + J_0(t) \frac{dT}{dt}(t) + J_1(t), \quad (17)$$

where

$$\begin{aligned} J_0(t) &= \frac{\Xi}{8\pi} \frac{d\mu}{dT} \sum_{N=1}^{N_1} \frac{p_N}{N} \int_0^{2\pi} d\varphi \int_0^\pi \frac{e^2(t, \vartheta, \varphi)}{1 - n(t, \vartheta, \varphi)} \sin \vartheta d\vartheta, \\ J_1(t) &= \frac{\mu \Xi}{8\pi} \sum_{N=1}^{N_1} \frac{p_N}{N} \int_0^{2\pi} d\varphi \int_0^\pi \frac{e^2(t, \vartheta, \varphi)}{[1 - n(t, \vartheta, \varphi)]^2} \frac{\partial n}{\partial t}(t, \vartheta, \varphi) \sin \vartheta d\vartheta. \end{aligned} \quad (18)$$

The function $J_0(t)$ in Eq. (18) determines the increment of the strain energy of a network associated with the dependence of the average rigidity per RHM, μ , on temperature, whereas the function $J_1(t)$ characterizes the increment of the potential energy of deformation driven by suppression and thermal activation of RHMs. Differentiation of Eq. (13) results in

$$\frac{\partial e}{\partial t}(t, \bar{l}) = \frac{1}{2[\bar{l} \cdot \hat{C}(t) \cdot \bar{l}]} \left[\bar{l} \cdot \frac{d\hat{C}}{dt}(t) \cdot \bar{l} \right] - \frac{\eta_N}{1 + \eta_N n(t, \bar{l})} \frac{\partial n}{\partial t}(t, \bar{l}). \quad (19)$$

It follows from Eq. (9) that

$$\frac{d\hat{C}}{dt}(t) = \bar{\nabla}^\circ \bar{v}(t) \cdot [\bar{\nabla}^\circ \bar{r}(t)]^\top + \bar{\nabla}^\circ \bar{r}(t) \cdot [\bar{\nabla}^\circ \bar{v}(t)]^\top,$$

where

$$\bar{v}(t) = \frac{d\bar{r}}{dt}(t)$$

is the velocity vector for the network. Bearing in mind that (Drozdov, 1996)

$$\bar{\nabla}^\circ \bar{v}(t) = \bar{\nabla}^\circ \bar{r}(t) \cdot \bar{\nabla}(t) \bar{v}(t),$$

where $\bar{\nabla}(t)$ is the gradient operator in the deformed state at time t , we obtain

$$\frac{d\hat{C}}{dt}(t) = 2\bar{\nabla}^\circ \bar{r}(t) \cdot \hat{D}(t) \cdot [\bar{\nabla}^\circ \bar{r}(t)]^\top, \quad (20)$$

where

$$\hat{D}(t) = \frac{1}{2} \left[\bar{\nabla}(t) \bar{v}(t) + (\bar{\nabla}(t) \bar{v}(t))^\top \right]$$

is the rate-of-strain tensor for the network. Equation (20) implies that

$$\bar{l} \cdot \frac{d\hat{C}}{dt}(t) \cdot \bar{l} = 2\bar{l} \cdot \bar{\nabla}^\circ \bar{r}(t) \cdot \hat{D}(t) \cdot [\bar{\nabla}^\circ \bar{r}(t)]^\top \cdot \bar{l} = 2\hat{F}(t, \bar{l}) : \hat{D}(t), \quad (21)$$

where

$$\hat{F}(t, \bar{l}) = [\bar{\nabla}^\circ \bar{r}(t)]^\top \cdot (\bar{l} \otimes \bar{l}) \cdot \bar{\nabla}^\circ \bar{r}(t) \quad (22)$$

is the generalized Finger tensor, the colon stands for convolution and $\otimes$ denotes tensor product. Substitution of Eqs. (19) and (21) into Eq. (17) results in the formula

$$\frac{dW}{dt}(t) = \hat{\Upsilon}(t) : \hat{D}(t) + J_0(t) \frac{dT}{dt}(t) - J_2(t), \quad (23)$$

where

$$\begin{aligned} \hat{\Upsilon}(t) &= \frac{\mu\Xi}{4\pi} \sum_{N=1}^{N_1} \frac{p_N}{N} \int_0^{2\pi} d\varphi \int_0^\pi \frac{e(t, \vartheta, \varphi)}{1 - n(t, \vartheta, \varphi)} \frac{\hat{F}(t, \vartheta, \varphi)}{\bar{l} \cdot \hat{C}(t) \cdot \bar{l}} \sin \vartheta d\vartheta, \\ J_2(t) &= \frac{\mu\Xi}{8\pi} \sum_{N=1}^{N_1} \frac{p_N}{N} \int_0^{2\pi} d\varphi \int_0^\pi \frac{h_N(t, \vartheta, \varphi)}{[1 - n(t, \vartheta, \varphi)]^2} \frac{\partial n}{\partial t}(t, \vartheta, \varphi) \sin \vartheta d\vartheta, \\ h_N(t, \vartheta, \varphi) &= e(t, \vartheta, \varphi) \left\{ \frac{2\eta_N[1 - n(t, \vartheta, \varphi)]}{1 + \eta_N n(t, \vartheta, \varphi)} - e(t, \vartheta, \varphi) \right\}. \end{aligned} \quad (24)$$

4 Constitutive equations

Observations evidence that the growth of temperature driven by periodic straining with small amplitudes (less than 10 %) is quite modest [it does not exceed 10 to 20 K for frequencies, f , in the range from 10^{-1} to 10^2 Hz, see Kar and Bhowmick (1997) and Lion (1998)]. This implies that the absolute temperature, T , remains rather close to its reference value, T_0 , and thermal expansion of the network may be disregarded. Under the hypothesis about affine deformation (which states that the rate-of-strain tensor for deformation of a specimen coincides with the rate-of-strain tensor for the network, $\hat{D}$), the first law of thermodynamics for an incompressible network reads (Coleman and Gurtin, 1997)

$$\frac{d\Phi}{dt} = \frac{1}{\rho} \left(\hat{\sigma}_d : \hat{D} - \bar{\nabla} \cdot \bar{q} \right) + r, \quad (25)$$

where ρ is mass density, $\hat{\sigma}_d$ is the deviatoric component of the Cauchy stress tensor $\hat{\sigma}$, $\bar{q}$ is the heat flux vector, Φ is the internal energy and r is the heat supply per unit mass. At relatively small increments of temperature, the density of a polymer, ρ , is treated as a constant. The Clausius–Duhem inequality is given by (Coleman and Gurtin, 1967)

$$\rho \frac{dQ}{dt} = \rho \frac{dS}{dt} + \bar{\nabla} \cdot \left(\frac{\bar{q}}{T} \right) - \frac{\rho r}{T} \geq 0, \quad (26)$$

where S is the entropy and Q is the entropy production per unit mass. Bearing in mind that

$$\bar{\nabla} \cdot \left(\frac{\bar{q}}{T} \right) = \frac{1}{T} \bar{\nabla} \cdot \bar{q} - \frac{1}{T^2} \bar{q} \cdot \bar{\nabla} T$$

and excluding the term $\bar{\nabla} \cdot \bar{q}$ from Eqs. (25) and (26), we find that

$$T \frac{dQ}{dt} = T \frac{dS}{dt} - \frac{d\Phi}{dt} + \frac{1}{\rho} \left(\hat{\sigma}_d : \hat{D} - \frac{1}{T} \bar{q} \cdot \bar{\nabla} T \right) \geq 0. \quad (27)$$

The internal energy per unit mass, Φ , is connected with the free (Helmholtz) energy per unit mass, Ψ , by the equality

$$\Phi = \Psi + ST. \quad (28)$$

It follows from Eqs. (27) and (28) that

$$T \frac{dQ}{dt} = -S \frac{dT}{dt} - \frac{d\Psi}{dt} + \frac{1}{\rho} \left(\hat{\sigma}_d : \hat{D} - \frac{1}{T} \bar{q} \cdot \bar{\nabla} T \right) \geq 0. \quad (29)$$

It is assumed that the free energy, Ψ , consists of the following four terms:

1. the free energy, Ψ_{eq} , of the network in the equilibrium stress-free state at the reference temperature T_0 (when the numbers of RHMs in a strand coincides with its initial value, N);
2. the free energy of thermal motion, Ψ_{th} , which is determined by the conventional formula

$$\Psi_{\text{th}} = (c - S_0)(T - T_0) - cT \ln \frac{T}{T_0},$$

where c is the specific heat (at relatively small increments of temperature, c is treated as a constant) and S_0 is the entropy per unit mass in the stress-free state at the reference temperature T_0 ;

3. the potential energy of deformation for the network, W , given by Eq. (16);
4. the increment of free energy, $\Delta\Psi$, induced by suppression and thermal activation of RHMs.

The latter term is associated with the excess free energy of a strand with the current number of RHMs, N_a , over that for the strand with the equilibrium number of RHMs, N . As a first approximation, the increment of the free energy for a strand with N RHMs, $\Delta\psi_N$, is given by

$$\Delta\psi_N = \frac{1}{2} \beta \mu (N_a - N)^2, \quad (30)$$

where β is a dimensionless parameter (which, in general, depends on temperature), and the average rigidity per RHM, μ , is introduced to ensure the correct dimension of the function $\Delta\psi_N$. Summing the increments of free energy, Eq. (30), for strands with various numbers of RHMs, N , and various guiding vectors, $\bar{l}$, and using Eqs. (3) and (15), we find that

$$\Delta\Psi(t) = \frac{\beta \mu \Xi}{8\pi} \sum_{N=1}^{N_1} N^2 p_N \int_0^{2\pi} d\varphi \int_0^\pi n^2(t, \vartheta, \varphi) \sin \vartheta d\vartheta.$$

The free energy per unit mass of the network, Ψ , reads

$$\Psi = \Psi_{\text{eq}} + (c - S_0)(T - T_0) - cT \ln \frac{T}{T_0} + W + \frac{\beta \mu \Xi}{8\pi} \sum_{N=1}^{N_1} N^2 p_N \int_0^{2\pi} d\varphi \int_0^\pi n^2 \sin \vartheta d\vartheta. \quad (31)$$

It follows from Eqs. (23), (24) and (31) that the derivative of the free energy per unit mass, Ψ , with respect to time, t , is given by

$$\frac{d\Psi}{dt} = \hat{\Upsilon} : \hat{D} + \left(\Delta S - S_0 - c \ln \frac{T}{T_0} \right) \frac{dT}{dt} - J, \quad (32)$$

where

$$\begin{aligned}
\Delta S(t) &= J_0(t) + \frac{\Xi}{8\pi} \frac{d(\beta\mu)}{dT} \sum_{N=1}^{N_1} N^2 p_N \int_0^{2\pi} d\varphi \int_0^\pi n^2 \sin \vartheta d\vartheta, \\
J(t) &= \frac{\mu\Xi}{8\pi} \sum_{N=1}^{N_1} \frac{p_N}{N} \int_0^{2\pi} d\varphi \int_0^\pi \frac{H_N(t, \vartheta, \varphi)}{[1 - n(t, \vartheta, \varphi)]^2} \frac{\partial n}{\partial t}(t, \vartheta, \varphi) \sin \vartheta d\vartheta, \\
H_N(t, \vartheta, \varphi) &= e(t, \vartheta, \varphi) \left\{ \frac{2\eta_N[1 - n(t, \vartheta, \varphi)]}{1 + \eta_N n(t, \vartheta, \varphi)} - e(t, \vartheta, \varphi) \right\} - 2\beta N^3 n(t, \vartheta, \varphi) [1 - n(t, \vartheta, \varphi)]^2. \quad (33)
\end{aligned}$$

Combining Eqs. (29) and (32), we find that

$$T \frac{dQ}{dt} = \frac{1}{\rho} (\hat{\sigma}_d - \rho \hat{\Upsilon}) : \hat{D} - \left(S - S_0 - c \ln \frac{T}{T_0} + \Delta S \right) \frac{dT}{dt} - \frac{1}{\rho T} \bar{q} \cdot \bar{\nabla} T + J \geq 0. \quad (34)$$

Applying the conventional reasoning to Eq. (34), see Coleman and Gurtin (1967), we find that the expressions in braces vanish. This implies the formula for the entropy per unit mass,

$$S = S_0 + c \ln \frac{T}{T_0} - \Delta S \quad (35)$$

and the relationship for the Cauchy stress tensor

$$\hat{\sigma}(t) = -P(t)\hat{I} + \frac{\rho\mu\Xi}{4\pi} \sum_{N=1}^{N_1} \frac{p_N}{N} \int_0^{2\pi} d\varphi \int_0^\pi \frac{e(t, \vartheta, \varphi)}{1 - n(t, \vartheta, \varphi)} \frac{\hat{F}(t, \vartheta, \varphi)}{\bar{l} \cdot \hat{C}(t) \cdot \bar{l}} \sin \vartheta d\vartheta, \quad (36)$$

where $P(t)$ is pressure. It follows from Eq. (35) that the quantity ΔS [given by Eqs. (18) and (33)] characterizes changes in the entropy per unit mass, S , driven by deformation of the network and suppression-activation of RHMs. Substitution of Eq. (22) into Eq. (36) results in the constitutive equation

$$\hat{\sigma}(t) = -P(t)\hat{I} + [\bar{\nabla}^\circ \bar{r}(t)]^\top \cdot \hat{B}(t) \cdot \bar{\nabla}^\circ \bar{r}(t) \quad (37)$$

with

$$\hat{B}(t) = \frac{\rho\mu\Xi}{4\pi} \sum_{N=1}^{N_1} \frac{p_N}{N} \int_0^{2\pi} d\varphi \int_0^\pi \frac{e(t, \vartheta, \varphi)}{1 - n(t, \vartheta, \varphi)} \frac{\bar{l} \otimes \bar{l}}{\bar{l} \cdot \hat{C}(t) \cdot \bar{l}} \sin \vartheta d\vartheta. \quad (38)$$

Combining Eqs. (34) to (36), we obtain

$$T \frac{dQ}{dt} = J - \frac{1}{\rho T} \bar{q} \cdot \bar{\nabla} T \geq 0. \quad (39)$$

The function $J(t)$ determines the rate of entropy production (per unit mass) induced by changes in the numbers of RHMs, whereas the last term on the right-hand side of Eq. (39) characterizes entropy production (per unit mass and unit time) driven by thermal conductivity. The function Q is assumed to be presented in the form

$$Q(t) = Q_{\text{th}}(t) + \Delta Q(t), \quad (40)$$

where Q_{th} describes the entropy production induced by thermal diffusivity and ΔQ determines the entropy production associated with the suppression-activation mechanism. We accept the conventional formula for the derivative of the function Q_{th} ,

$$\frac{dQ_{\text{th}}}{dt}(t) = \frac{\kappa(\bar{\nabla} T)^2}{\rho T^2}, \quad (41)$$

where $\kappa > 0$ is a constant thermal diffusivity, and $(\bar{\nabla} T)^2 = \bar{\nabla} T \cdot \bar{\nabla} T$. It follows from Eqs. (39) to (41) that

$$T \frac{d\Delta Q}{dt} = J - \frac{1}{\rho T} (\bar{q} + \kappa \bar{\nabla} T) \cdot \bar{\nabla} T \geq 0. \quad (42)$$

Bearing in mind that this inequality holds for an arbitrary thermo-mechanical process, we find that the expression in braces vanishes, which results in the Fourier law for the heat flux vector

$$\bar{q}(t) = -\kappa \bar{\nabla}(t)T(t). \quad (43)$$

Equations (42) and (43) yield

$$T \frac{d\Delta Q}{dt} = J \geq 0. \quad (44)$$

We postulate that the function ΔQ is given by

$$\Delta Q(t) = \frac{1}{4\pi} \sum_{N=1}^{N_1} \Xi_N \int_0^{2\pi} d\varphi \int_0^\pi \Delta Q_N(t, \vartheta, \varphi) \sin \vartheta d\vartheta, \quad (45)$$

where $\Delta Q_N(t, \bar{l})$ characterizes the energy dissipation per strand containing N RHMs and directed along vector $\bar{l}$. To construct the functions ΔQ_N , we refer to the conventional expression for the entropy production $\tilde{Q}$ in an incompressible viscous fluid

$$T \frac{d\tilde{Q}}{dt} = \zeta \hat{D} : \hat{D}, \quad (46)$$

where ζ stands for viscosity. Equation (46) means that the rate of entropy production per unit mass is proportional to the square of the relative velocity (which is characterized by the rate-of-strain tensor $\hat{D}$). By analogy with this relation, we postulate that the expression

$$T(t) \frac{\partial \Delta Q_N}{\partial t}(t, \vartheta, \varphi)$$

is proportional to the square of the relative rate of changes in the number of RHMs. According to Eq. (3), this rate is given by

$$-\frac{1}{N_a} \frac{dN_a}{dt} = \frac{1}{1-n} \frac{dn}{dt}. \quad (47)$$

With reference to Clarke et al. (2000), we assume that energy can dissipate at junction points only, which implies that Eq. (47) should be multiplied by the probability that the activated (suppressed) segment is located at the end of a strand (this probability equals $2/N$ for a strand containing N RHMs). As a result, we obtain

$$T(t) \frac{\partial \Delta Q_N}{\partial t}(t, \vartheta, \varphi) = \frac{\tilde{\kappa}}{N^2} [1 - n(t, \vartheta, \varphi)]^{-2} \left[\frac{\partial n}{\partial t}(t, \vartheta, \varphi) \right]^2, \quad (48)$$

where $\tilde{\kappa}$ is a positive coefficient independent of the number of RHMs in a strand. Substituting expressions (45) and (48) into Eq. (44) and equating coefficients at the derivative $\partial n / \partial t$ on the left and right hand sides on the resulting equality, we arrive at the kinetic equation for the function $n(t, \vartheta, \varphi)$,

$$\frac{\partial n}{\partial t}(t, \vartheta, \varphi) = \frac{\mu N}{2\tilde{\kappa}} H_N(t, \vartheta, \varphi).$$

It follows from this formula and Eq. (33) that

$$\frac{\partial n}{\partial t}(t, \vartheta, \varphi) = \alpha_{1N} e(t, \vartheta, \varphi) \left\{ \frac{2\eta_N [1 - n(t, \vartheta, \varphi)]}{1 + \eta_N n(t, \vartheta, \varphi)} - e(t, \vartheta, \varphi) \right\} - \alpha_{2N} n(t, \vartheta, \varphi) [1 - n(t, \vartheta, \varphi)]^2, \quad (49)$$

where

$$\alpha_{1N} = a_1 N, \quad \alpha_{2N} = a_2 N^4, \quad a_1 = \frac{\mu}{2\tilde{\kappa}}, \quad a_2 = \frac{\mu\beta}{\tilde{\kappa}}. \quad (50)$$

It follows from Eq. (3) that the initial condition for Eq. (49) reads

$$n(t, \vartheta, \varphi) \Big|_{t=0} = 0. \quad (51)$$

Relations (13), (37), (38), (49) and (51) provide a set of constitutive equations for a rubbery polymer at finite strains. The behavior of the coefficients (50) in kinetic equation (49) is unusual. The parameter α_{1N} linearly increases with N , which means that suppression of RHMs occurs more rapidly in long strands than in short ones. On the other hand, the quantity α_{2N} grows as the fourth power of N , which implies that the concentration of RHMs in long strands remains sufficiently large.

5 Constitutive equations at small strains

We now simplify the constitutive equations for the case of small strains. According to Eq. (49), the condition $|e| \ll 1$ ensures small changes in the concentrations of RHMs, $n \ll 1$. Introducing the strain tensor $\hat{e}$ by the conventional formula

$$\hat{e}(t) = \frac{1}{2}[\hat{C}(t) - \hat{I}],$$

we find from Eq. (13) that

$$e(t, \bar{l}) = \frac{1}{2} \ln \left[1 + 2\bar{l} \cdot \hat{e}(t) \cdot \bar{l} \right] - \ln \left[1 + \eta_N n(t, \bar{l}) \right].$$

Neglecting terms beyond the first order of smallness compared to $|\hat{e}|$ and n , we obtain

$$e(t, \bar{l}) = \bar{l} \cdot \hat{e}(t) \cdot \bar{l} - \eta_N n(t, \bar{l}). \quad (52)$$

It follows from Eqs. (49) and (52) that with the required level of accuracy, n satisfies the differential equation

$$\frac{\partial n}{\partial t}(t, \bar{l}) = 2\alpha_{1N}\eta_N \bar{l} \cdot \hat{e}(t) \cdot \bar{l} - (2\alpha_{1N}\eta_N^2 + \alpha_{2N})n(t, \bar{l}). \quad (53)$$

The solution of Eq. (53) with initial condition (51) reads

$$n(t, \bar{l}) = 2\alpha_{1N}\eta_N \int_0^t \exp \left[-(2\alpha_{1N}\eta_N^2 + \alpha_{2N})(t - \tau) \right] \bar{l} \cdot \hat{e}(\tau) \cdot \bar{l} \, d\tau.$$

This equality together with Eq. (52) implies that

$$e(t, \bar{l}) = \bar{l} \cdot \left\{ \hat{e}(t) - 2\alpha_{1N}\eta_N^2 \int_0^t \exp \left[-(2\alpha_{1N}\eta_N^2 + \alpha_{2N})(t - \tau) \right] \hat{e}(\tau) \, d\tau \right\} \cdot \bar{l}. \quad (54)$$

Substituting Eq. (52) into Eqs. (37) and (38) and neglecting terms beyond the first order of smallness, we find that

$$\begin{aligned} \hat{\sigma}(t) = & -P(t)\hat{I} + \frac{\rho\mu\Xi}{4\pi} \sum_{N=1}^{N_1} \frac{p_N}{N} \int_0^{2\pi} d\varphi \int_0^\pi (\bar{l} \otimes \bar{l}) \sin \vartheta d\vartheta \\ & \bar{l} \cdot \left\{ \hat{e}(t) - 2\alpha_{1N}\eta_N^2 \int_0^t \exp \left[-(2\alpha_{1N}\eta_N^2 + \alpha_{2N})(t - \tau) \right] \hat{e}(\tau) \, d\tau \right\} \cdot \bar{l}. \end{aligned} \quad (55)$$

To calculate the integral, we introduce a Cartesian coordinate frame $\{x_i\}$ with base vectors $\bar{e}_i$ which are directed along the eigenvectors of the symmetric tensor $\hat{e}$ and obtain

$$\hat{e}(t) = \epsilon_1(t)\bar{e}_1\bar{e}_1 + \epsilon_2(t)\bar{e}_2\bar{e}_2 + \epsilon_3(t)\bar{e}_3\bar{e}_3, \quad (56)$$

where ϵ_i is the i th eigenvalue of $\hat{e}$. The unit vector $\bar{l}$ is given by

$$\bar{l} = \cos \vartheta \bar{e}_1 + \sin \vartheta (\cos \varphi \bar{e}_2 + \sin \varphi \bar{e}_3), \quad (57)$$

It follows from Eqs. (56) and (57) that

$$\bar{l} \cdot \hat{e}(t) \cdot \bar{l} = \epsilon_1(t) \cos^2 \vartheta + \left[\epsilon_2(t) \cos^2 \varphi + \epsilon_3(t) \sin^2 \varphi \right] \sin^2 \vartheta.$$

Equation (57) implies that the tensor $\bar{l} \otimes \bar{l}$ is determined by the matrix

$$\bar{l} \otimes \bar{l} = \begin{bmatrix} \cos^2 \vartheta & \sin \vartheta \cos \vartheta \cos \varphi & \sin \vartheta \cos \vartheta \sin \varphi \\ \sin \vartheta \cos \vartheta \cos \varphi & \sin^2 \vartheta \cos^2 \varphi & \sin^2 \vartheta \sin \varphi \cos \varphi \\ \sin \vartheta \cos \vartheta \sin \varphi & \sin^2 \vartheta \sin \varphi \cos \varphi & \sin^2 \vartheta \sin^2 \varphi \end{bmatrix}.$$

After simple algebra we find that

$$\frac{1}{4\pi} \int_0^{2\pi} d\varphi \int_0^\pi (\bar{l} \otimes \bar{l}) \sin \vartheta d\vartheta \bar{l} \cdot \hat{\epsilon} \cdot \bar{l} = \frac{1}{15} \begin{bmatrix} 3\epsilon_1 + \epsilon_2 + \epsilon_3 & 0 & 0 \\ 0 & \epsilon_1 + 3\epsilon_2 + \epsilon_3 & 0 \\ 0 & 0 & \epsilon_1 + \epsilon_2 + 3\epsilon_3 \end{bmatrix}.$$

This equality together with the incompressibility condition,

$$\epsilon_1 + \epsilon_2 + \epsilon_3 = 0,$$

results in the formula

$$\frac{1}{4\pi} \int_0^{2\pi} d\varphi \int_0^\pi (\bar{l} \otimes \bar{l}) \sin \vartheta d\vartheta \bar{l} \cdot \hat{\epsilon} \cdot \bar{l} = \frac{2}{15} \hat{\epsilon}.$$

Substituting this expression into Eq. (55), we arrive at the stress-strain relation

$$\hat{\sigma}(t) = -P(t)\hat{I} + \frac{2\rho\mu\Xi}{15} \sum_{N=1}^{N_1} \frac{p_N}{N} \left[\hat{\epsilon}(t) - \zeta_N \Gamma_N \int_0^t \exp(-\Gamma_N(t-\tau)) \hat{\epsilon}(\tau) d\tau \right] \quad (58)$$

with

$$\Gamma_N = 2\alpha_{1N}\eta_N^2 + \alpha_{2N}, \quad \zeta_N = \frac{2\alpha_{1N}\eta_N^2}{2\alpha_{1N}\eta_N^2 + \alpha_{2N}}. \quad (59)$$

It follows from Eq. (58) that the conventional shear modulus of a rubbery polymer at small strains is given by

$$G_0 = \frac{\rho\mu\Xi}{15} \sum_{N=1}^{N_1} \frac{p_N}{N}.$$

This equation establishes correspondence between the material parameters at the micro-level (μ and N) and those at the macro-level (G_0 and ρ). Formula (58) is equivalent to phenomenological relations (1) and (2). An important advantage of Eq. (58) compared to those equations is that the relaxation rates Γ_N [inverse to the characteristic times τ_N is Eq. (2)] and the coefficients ζ_N [analogs of the relaxation strengths ξ_N is Eq. (2)] are not arbitrary, but are determined by Eq. (59).

6 Uniaxial extension of a specimen

We consider a specimen in the form of a rectilinear bar whose points refer to Cartesian coordinates $\{x_i\}$ with unit vectors $\bar{e}_i$. At uniaxial extension of an incompressible material, the strain tensor $\hat{\epsilon}$ is given by

$$\hat{\epsilon} = \epsilon \left[\bar{e}_1 \bar{e}_1 - \frac{1}{2} (\bar{e}_2 \bar{e}_2 + \bar{e}_3 \bar{e}_3) \right], \quad (60)$$

where ϵ is the longitudinal strain. Substitution of Eq. (60) into Eq. (58) implies that the stress tensor reads

$$\hat{\sigma} = \sigma \bar{e}_1 \bar{e}_1 + \sigma_0 (\bar{e}_2 \bar{e}_2 + \bar{e}_3 \bar{e}_3),$$

where

$$\begin{aligned} \sigma(t) &= -P(t) + \frac{2\rho\mu\Xi}{15} \sum_{N=1}^{N_1} \frac{p_N}{N} \left[\epsilon(t) - \zeta_N \Gamma_N \int_0^t \exp(-\Gamma_N(t-\tau)) \epsilon(\tau) d\tau \right], \\ \sigma_0(t) &= -P(t) - \frac{\rho\mu\Xi}{15} \sum_{N=1}^{N_1} \frac{p_N}{N} \left[\epsilon(t) - \zeta_N \Gamma_N \int_0^t \exp(-\Gamma_N(t-\tau)) \epsilon(\tau) d\tau \right]. \end{aligned} \quad (61)$$

It follows from the boundary condition on the lateral surface of the specimen that $\sigma_0(t) = 0$. Combining this equality with Eq. (61), we arrive at the formula for the longitudinal stress

$$\sigma(t) = K \sum_{N=1}^{N_1} \frac{p_N}{N} \left[\epsilon(t) - \zeta_N \Gamma_N \int_0^t \exp(-\Gamma_N(t-\tau)) \epsilon(\tau) d\tau \right] \quad (62)$$

with

$$K = \frac{\rho\mu\Xi}{5}.$$

The parameter K is proportional to Young's modulus, E_0 , which is determined by the formula

$$E_0 = K \sum_{N=1}^{N_1} \frac{p_N}{N}. \quad (63)$$

To study the response of a specimen to periodic stretching, we set

$$\epsilon(t) = \Delta \exp(i\omega t), \quad (64)$$

where $i = \sqrt{-1}$, Δ is the amplitude and ω is the frequency of oscillations, substitute expression (64) into Eq. (62), and obtain

$$\begin{aligned} \sigma(t) &= K \sum_{N=1}^{N_1} \frac{p_N}{N} \left\{ 1 - \zeta_N \Gamma_N \int_0^t \exp[-(\Gamma_N + i\omega)(t - \tau)] d\tau \right\} \epsilon(t) \\ &= K \sum_{N=1}^{N_1} \frac{p_N}{N} \left\{ 1 - \zeta_N \Gamma_N \int_0^t \exp[-(\Gamma_N + i\omega)s] ds \right\} \epsilon(t). \end{aligned} \quad (65)$$

Adopting the conventional approach to the analysis of steady oscillations, we replace the upper limit of integration in Eq. (65) by infinity, calculate the integral, introduce the complex modulus

$$E^* = \frac{\sigma}{\epsilon},$$

and find that

$$E^*(\omega) = K \sum_{N=1}^{N_1} \frac{p_N}{N} \left(1 - \frac{\zeta_N \Gamma_N}{\Gamma_N + i\omega} \right).$$

Bearing in mind that

$$E^* = E' + iE'',$$

where E' is the storage modulus and E'' is the loss modulus, we arrive at the formulas

$$E'(\omega) = K \sum_{N=1}^{N_1} \frac{p_N}{N} \frac{(1 - \zeta_N) \Gamma_N^2 + \omega^2}{\Gamma_N^2 + \omega^2}, \quad E''(\omega) = K \sum_{N=1}^{N_1} \frac{p_N}{N} \frac{\zeta_N \Gamma_N \omega}{\Gamma_N^2 + \omega^2}. \quad (66)$$

Equations (66) are rather standard (except for the presence of the multiplier p_N/N) and may be found in textbooks on the mechanics of polymers (see, e.g., Ferry, 1980). The novelty of our approach is that it provides a new scaling for the relaxation rates, Γ_N , and the relaxation strengths, ζ_N . It follows from Eqs. (12), (50) and (59) that

$$\Gamma_N = aN^2 + bN^4, \quad \zeta_N = \frac{a}{a + bN^2}, \quad (67)$$

where

$$a = 2a_1 \tilde{\eta}^2 = \frac{\mu}{\tilde{\kappa}} \tilde{\eta}^2, \quad b = a_2 = \frac{\mu}{\tilde{\kappa}} \beta. \quad (68)$$

The advantage of Eqs. (14), (66) and (67) is that they contain only 5 adjustable parameters (which, in general, are temperature-dependent): the elastic modulus K , the average number of RHMs per strand in the equilibrium state $\tilde{N}$, the standard deviation of the number of RHMs Σ , the rate of suppression of RHMs a , and the rate of activation for frozen segments b (the parameter N_1 is chosen in such a way that p_{N_1} becomes negligible compared to unity; for the quasi-Gaussian distribution (14), it suffices to set $N_1 > \tilde{N} + 3\Sigma$). This number is essentially less than the number of adjustable constants conventionally employed to fit experimental data [for example, we refer to Wu and Liechti (2000), where 14 constants in Eq. (2), τ_N , were fixed *a priori* and the other 14 constants, ξ_N , were found by the least-square algorithm].

7 Comparison with experimental data

To verify the constitutive equations (14), (66) and (67), we fit experimental data for a carbon black filled natural rubber vulcanizate with the filler content 50 phr (parts per hundred parts of rubber) and the glass transition temperature $T_g = 220$ K. For a detailed description of specimens and the experimental procedure, the reader is referred to Lion (1998).

We begin with matching experimental data in dynamic tensile tests at the temperature $T = 253$ K, the smallest amplitude of oscillations $\Delta = 0.006$ and the frequency $f = \omega/(2\pi)$ in the range from 10^{-1} to 10^2 Hz. Given a modulus K , the quantities a , b , $\tilde{N}$ and Σ that ensure the best quality of approximation for the storage modulus, E' , are found by the steepest-descent procedure. The parameter K is determined by the least-squares algorithm. Afterwards, we fix the constants a and b found by matching observations for $E'(\omega)$ with $\Delta = 0.006$ and fit experimental data for other amplitudes of oscillations, $\Delta = 0.011$, $\Delta = 0.028$ and $\Delta = 0.056$, by using three adjustable parameters: K , $\tilde{N}$ and Σ . Experimental data and results of numerical analysis (with $N_1 = 500$) are plotted in Figure 2. The same procedure of fitting is repeated for three other temperatures: $T = 296$, $T = 333$ and $T = 373$ K. Appropriate results are depicted in Figures 3 to 5. Figures 2 to 5 demonstrate fair agreement between observations and results of numerical simulation at all temperatures under consideration.

The average number of RHMs in an equilibrated strand, $\tilde{N}$, is plotted versus the amplitude of oscillations, Δ , in Figures 7 to 10. Experimental data are approximated by the phenomenological relation

$$\tilde{N} = \tilde{N}_0 + \tilde{N}_1 \Delta, \quad (69)$$

where the constants $\tilde{N}_i$ are found by the least-squares technique. Figures 6 to 9 show that Eq. (69) correctly predicts observations in the entire rang of amplitudes, except for a region of very small strains. The latter may be explained by insufficient accuracy of the dynamic tests with extremely small amplitudes on preloaded specimens (with the compression strain of about 10 %).

The standard deviation of the number of RHMs in a strand, Σ , is depicted in Figures 10 to 13 as a function of the amplitude of oscillations, Δ . Observations are approximated by the linear dependence

$$\Sigma = \Sigma_0 + \Sigma_1 \Delta, \quad (70)$$

where adjustable parameters Σ_i are determined by using the least-squares algorithm. Equation (70) provides an acceptable quality of matching observations in the entire region of amplitudes of oscillations, Δ , except for very low intensities of strains.

The parameters $\tilde{N}_i$ and Σ_i found at various temperatures are collected in Table 1 which demonstrates that the average number of RHMs per strand grows with the amplitude of straining (in accord with the intuitive picture that mechanical loading increases the molecular mobility of chains).

The quantities a and b are plotted versus temperature T in Figure 14. Because the suppression-activation mechanism for RHMs is assumed to be driven by thermal fluctuations, the rates of transformation are approximated by the Arrhenius dependences,

$$a = \tilde{a} \exp\left(-\frac{E_a}{RT}\right), \quad b = \tilde{b} \exp\left(-\frac{E_b}{RT}\right),$$

where $\tilde{a}$ and $\tilde{b}$ are appropriate rates at high temperature, E_a and E_b are activation energies, and R is the universal gas constant. It follows from these formulas that

$$\log a = a_0 - \frac{a_1}{T}, \quad \log b = b_0 - \frac{b_1}{T}, \quad (71)$$

where

$$a_0 = \log \tilde{a}, \quad a_1 = \frac{E_a}{R \ln 10}, \quad b_0 = \log \tilde{b}, \quad b_1 = \frac{E_b}{R \ln 10}, \quad \log = \log_{10}.$$

Figure 14 demonstrates an acceptable agreement between experimental data and their approximation by Eqs. (71) with adjustable parameters a_i and b_i , except for the region of high temperatures, where relations (71) overestimate the transformation rates. The latter may be explained by the following reasons:

1. the average radius of a tube which reflects constraints on the motion of a strand imposed by surrounding macromolecules strongly increases at elevated temperatures, which implies that transformations of RHMs are slowed down;
2. equilibration of an elastomer specimen at temperatures near $T = 100$ °C before mechanical tests results in a noticeable scission of chains (see, e.g., Palmas et al., 2001), which is beyond the scope of the present model.

The parameter b grows with temperature faster than a ($b_1 = 2.32 \cdot 10^3$ versus $a_1 = 1.48 \cdot 10^3$). Assuming the quantity $\tilde{\eta}$ to depend on temperature rather weakly (as a power law, but not in the exponential fashion), we find from Eq. (68) that β substantially increases with temperature. The latter means that the excess free energy caused by suppression and activation of RHMs, see Eq. (30), is a strongly increasing function of temperature.

Another important conclusion may be drawn from results listed in Table 1 which show that the parameters $\tilde{N}_1$ and Σ_1 increase with temperature (the only exception is the value of N_1 at the lowest temperature, $T = 253$ K, when the elastomer demonstrates quasi-brittle response). This implies that the influence of the amplitude of oscillations, Δ , on the distribution of strands with various numbers of RHMs becomes stronger with temperature.

It is worth noting that the parameters $\tilde{N}$ and Σ corresponding to the smallest amplitude of straining, $\Delta = 0.006$, are practically independent of temperature, see data collected in Table 2. This means that mechanical loading may be thought of as the main reason for changes in the distribution of RHMs. The effect of mechanical factors is enhanced at elevated temperatures and is weakened at relatively low temperatures, in agreement with the assumption about the entropic nature of transformations of RHMs.

8 Discussion

Our purpose now is to develop conditions under which the viscoelastic response of rubbery polymers is substantially weakened and to establish some correspondence between these relations and observations exposed in the introductory section.

It follows from Eqs. (67) and (68) that

$$\zeta_N = \left(1 + \frac{\beta}{\tilde{\eta}^2} N^2\right)^{-1}. \quad (72)$$

Combining Eqs. (12), (66) and (72), replacing the parameter N by its average value, $\tilde{N}$ and assuming Γ_N to be of the same order of magnitude as the frequency of oscillations (which results in a very rough estimate), we conclude that the mechanical damping of an elastomer disappears ($E'' \rightarrow 0$), provided that

$$\beta \tilde{N}^2 \left(\frac{\tilde{\delta}}{\delta^\circ}\right)^2 \gg 1. \quad (73)$$

Based on Eq. (73) one can speculate that the weak damping reported by Leblanc and Cartault (2001) is associated with a large average number of RHMs per strand, $\tilde{N}$, in uncured styrene–butadiene composites. This conclusion does not contradict the presence of filler particles in these compounds, because at the length scale of RHMs (which is less than the length-scale of a strand by two orders of magnitude, see Table 1), the influence of particles is negligible.

Observations by Liang et al. (1999) may be explained within the framework of Eq. (73) by the large energy necessary for suppression of a RHM, β , in a polymer composite with a high degree of crystallinity and a relatively small content of elastomer (about 10 %).

To explain experimental results reported by Aksel and Hübner (1996) and Clarke et al. (2000), we consider uniaxial relaxation test with a small strain ϵ_0 ,

$$\epsilon(t) = 0 \quad (t < 0), \quad \epsilon(t) = \epsilon_0 \quad (t > 0), \quad (74)$$

substitute expression (74) into Eq. (62), introduce the relaxation modulus

$$E(t) = \frac{\sigma(t)}{\epsilon_0},$$

and find that

$$E(t) = K \sum_{N=1}^{N_1} \frac{p_N}{N} \left[1 - \zeta_N \left(1 - \exp(-\Gamma_N t) \right) \right]. \quad (75)$$

It follows from Eq. (75) that changes in the relaxation modulus, $E(t)$, are negligible when either the parameters ζ_N are small compared to unity [which is described by Eq. (73)] or the characteristic times of relaxation $\tau_N = \Gamma_N^{-1}$ are small compared to the characteristic time of the test, τ_0 . Equations (12), (67) and (68) imply that the latter condition is given by

$$\frac{\tilde{\kappa}}{\mu N^2} \left(\frac{\tilde{\delta}}{\delta^0} \right)^2 \zeta_N \ll \tau_0 \quad (N = 1, \dots, N_1).$$

This inequality implies that no viscoelastic response is observed in a test (even if ζ_N is of the order of unity) under the condition

$$\frac{\tilde{\kappa}}{\mu \tau_0} \ll 1. \quad (76)$$

Based on Eq. (76), one can speculate that the absence of time-dependent response in experiments on polybutadiene rubber at room temperature (Aksel and Hübner, 1996) and polyacrylate rubber at elevated temperatures (Clarke et al., 2000) is associated with slow rates of entropy production in these polymers [small $\tilde{\kappa}$ is Eq. (48)], whereas noticeable relaxation of stresses observed in natural rubber at $T = 80^\circ \text{C}$ (Clarke et al., 2000) may be explained by a substantial increase in the dimensionless ratio $\tilde{\kappa}/(\mu \tau_0)$ with temperature.

9 Concluding remarks

Constitutive equations have been derived for the time-dependent response of rubbery polymers at finite strains. A particle-reinforced elastomer is modeled as a network of long chains bridged by permanent junctions (chemical crosslinks, entanglements and filler particles). In agreement with the tube concept, a strand between two neighboring junctions is supposed to be confined to a tube which describes constraints on its micro-motion imposed by surrounding macromolecules. Unlike the conventional approach that postulates a constant cross-section of the tube, its radius is assumed to change substantially with the longitudinal coordinate. The waviness of the tube's surface is associated with local heterogeneities of the polymer (both in space and time) which impose additional constraints on the motion of macromolecules. This implies that a strand may be treated as a sequence of threads (RHMs) whose thermal motion is unconstrained (in the sense that they go through all possible configurations during the characteristic time of experiment) and highly constrained segments with a negligible entropy (which correspond to the bottle-neck points of the tube). Thermal fluctuations result in reconstruction of the tube surface, which is reflected by freezing of some RHMs and activation of frozen segments. The viscoelastic behavior of a rubbery polymer is associated with thermally agitated changes in the concentrations of RHMs.

The stress-strain relations at finite strains and the kinetic equations for the numbers of RHMs in strands are developed by using the laws of thermodynamics. At small strains, these relations are reduced to the integral constitutive equation in linear viscoelasticity (1) with the relaxation kernel in the form of a truncated Prony series (2). Unlike the phenomenological approach which provides no information about the relaxation spectrum, a novel scaling law (67) is derived for the characteristic times of relaxation. 5 adjustable parameters of the model are found by fitting experimental data in tensile dynamic tests for a carbon black filled natural rubber vulcanizate at various temperatures, amplitudes and frequencies of oscillations. Fair agreement is demonstrated between observations and results of numerical simulation. It is shown that the experimental constants are altered by temperature and amplitude of straining in a physically plausible way.
